

Implementation of Motzkin-Burger algorithm in Maple

P.A. Burovsky

burp@front.ru

Abstract

Subject of this paper is an implementation of a well-known Motzkin-Burger algorithm, which solves the problem of finding the full set of solutions of a system of linear homogeneous inequalities. There exist a number of implementations of this algorithm, but there was no one in Maple, to the best of the author's knowledge.

1 The problem

Consider a linear homogeneous system of inequalities with rational coefficients

$$l_j(x) = a_{j1}x_1 + \dots + a_{jn}x_n \leq 0, \quad a_{ji} \in \mathbb{Q}, \quad (j = 1, \dots, m). \quad (1)$$

Let r be the rank of the matrix of (1).

Recall some common facts from the theory of convex sets (see for example, [1]). Every solution set $X_1, \dots, X_p$ of a system (1) generates a convex cone C of solutions

$$k_1X_1 + \dots + k_pX_p, \quad k_i \geq 0. \quad (2)$$

We call a finite set of solutions $X_1, \dots, X_p \in \mathbb{Q}^n$ a set of generators for C if every element of C is a conical combination (2) of $X_1, \dots, X_p$. Hereinafter we will consider the minimal sets of generators only, i.e. such that none of the $X_i, i = 1, \dots, p$ is expressed from the others with positive coefficients. We call d the dimension of a cone C if d is the dimension of the minimal linear space spanned by C .

A solution locus of each inequality is a half-space of $\mathbb{Q}^n$. For any subsystem $\{l_j(x) \leq 0, j \in J\}$ of (1) its solution set is a convex polyhedral cone. The faces of the latter are the intersections of C with solution loci of some equation subsystems $\{l_j(x) = 0, j \in I \subseteq J\}$ with linearly independent left-hand sides.

The problem discussed in this paper is to solve (1) over $\mathbb{Q}^n$. This problem is closely related to the following one. Extend the system (1) by a new inequality

$$l(x) = a_1x_1 + \dots + a_nx_n \leq 0. \quad (3)$$

Not all the points of the cone C satisfy (3), thus the system (1) together with (3) define a new cone C^* . We are interested in computing the set of generators

for C^* given the set of generators for C . The Motzkin-Burger algorithm solves this problem.

The iteration of the Motzkin-Burger algorithm solves the first problem by means of extending the trivial system $\{0 \leq 0\}$ by the inequalities of (1) one by one.

2 Algorithm description

2.1 Theoretical study

Let us recall some well-known facts (generally following [1], [2], [3]).

The set of generators for a cone C^* consists of generators for cone C (which satisfy the inequality $l(x) < 0$) and the whole set of generators for cone $C \cap H$ where $H := \{l(x) = 0\}$. Thus, in order to compute the cone C^* we need to study both the structure of the cone C and structure of the intersection.

The cone C is a Minkovsky sum of its linear subspace L and the strongly convex cone P (that is the cone with apex at the origin and contain no line through the origin). Vectors u of the base U of L satisfy $\{l_j(u) = 0, j = 1, \dots, m\}$, whereas any element v of set V of generators of P satisfies $l_j(v) < 0$ for at least one j .

Let us denote vectors X belonging to U or V by X^+ if $l(X) > 0$, X^- if $l(X) < 0$ and X^0 if $l(X) = 0$. Also denote the linear subspace of the new cone with its base and the strongly convex cone of the new cone with its set of generators by L^* , U^* , P^* , V^* , respectively. Hence the vector u^0 belongs to U^* , while u^- , v^0 and v^- belong to V^* . Although, $\{u \in U : l(u) = 0\}$ is not U^* . By discarding all u^+ -s and v^+ -s we lose a number of generators for the cone C and have to be replaced them by the whole set of generators for $H \cap C$.

Since $H \cap C = (H \cap L) \cup (H \cap P)$ we can describe how to convert U to U^* and V to V^* separately.

There are two cases with respect to the intersection $H \cap L$: $H \cap L = L$ or $H \cap L \neq L$. In the first case, $U^* = U$.

In the second case the new inequality (3) reduces the dimension of L by one. Choose one $u^- \in U$ (if there is no such vector in U , take $-u^+$). Let us form $\dim L - 1$ pairs of vectors u^- and $u_j \in U \setminus \{u^-\}$. For every pair consider the conic combinations

$$au^- + bu_j, \quad a, b \geq 0. \quad (4)$$

The intersection of H with the cone (4) is the ray of positive multiplies of

$$u_j^* := -l(u^-)u_j + l(u_j)u^-. \quad (5)$$

It is clear that $l(u_j^*) = 0$. Thus, $\dim L - 1$ vectors u_j^* are the base of L^* . Note that the representation of the base of L is not unique since we can choose different vectors for u^- if they exist.

The conversion of V to V^* also depends on existence of abovementioned u^- . The element u^- belongs to V^* if it exists. New inequality (3) induces the affine

transformation

$$-l(u^-)v + l(v)u^- \quad (6)$$

of elements $v \in V$ that results in that every vector (6) satisfies (3). It is evident that the set $\{u^-, -l(u^-)v + l(v)u^- \text{ for all } v \in V\}$ is minimal in the abovementioned sense, thus the latter is the set of generators V^* .

If there exist no such $u^- \in U$, the transformation (6) of V is impossible. The new inequality separates P into two parts. As already was mentioned, the elements v^- belong to V^* .

To find all the vectors that lie in H let us consider any pair $v^-, v^+ \in V$. For this pair the combination

$$v_k^* := -l(v^-)v^+ + l(v^+)v^- \quad (7)$$

lies in H . The set of all v_k^* -s generates the convex polyhedral cone in H , but there are too many elements of $\{v_k^*\}$ for it to be the set of generators for the latter cone. The minimal faces that contain a pair of generators are exactly two-dimensional ones. Therefore, in order to avoid the superfluous solutions we only need to reject all the pairs of generators that are not lying on faces of dimension 2.

Checking if two vectors lie on a face of dimension 2 may be done in two ways. The first way is to check whether there exists $\{l_j(x), j \in J, |J| = r - 2\}$ with linear independent $l_j(x)$ such that $l_j(v^-) = l_j(v^+) = 0$ holds true for all $j \in J$. The second way is to check there exist no third $v \in V$ such that $l_j(v) = 0$ for all j such that $l_j(v^-) = l_j(v^+) = 0$ (are not taken into account the rank r nor linear independence of l_j -s).

We therefore come to the algorithm that solves a system of linear inequalities over $\mathbb{Q}^n$:

Input: $S := \{l_1(x), \dots, l_m(x)\}$ — the left-hand sides of the inequalities of (1), n — the space dimension.
Output: $U = \{u_1, \dots, u_t\}$ — the base of the maximal linear subspace L of the solution cone of (1),
 $V = \{v_1, \dots, v_s\}$ — the set of generators for the strongly convex cone P of the solutions of the system (1).

1. $U_{current} := \{(1, \dots, 0), \dots, (0, \dots, 1)\};$
2. $V_{current} := \emptyset;$
3. $S_{current} := \{0 \leq 0\};$
4. $i := 1;$
5. $l := l_i(x);$
6. **if** $\exists u \in U_{current}: l(u) \neq 0$, **then**
 $U_{current} := \{l(u)u_i - l(u_i)u, \quad u_i \in U_{current}\};$
 $n := -(l(u)/|l(u)|)u;$
 $V_{current} := \{n, -l(n)v_i + l(v_i)n, \quad v_i \in V_{current}\};$
7. **else**
 $V_{current}^1 := \{v \in V_{current} \mid l(v) \leq 0\}; V_{current}^2 := \emptyset;$

```

for  $\forall (v_k, v_s) \in V_{current}^2 : l(v_k) < 0, l(v_s) > 0$  do
     $S^* := \{l_j(x) \in S_{current} \mid l_j(v_k) = l_j(v_s) = 0\};$ 
    if  $S^* \neq \emptyset$  then
        for  $\forall v \in V_{current} \setminus \{v_k, v_s\}$ 
            for  $\forall l_j(x) \in S^*$  do
                if  $l_j(v) \neq 0$  then
                     $V_{current}^2 := V_{current}^2 \cup \{-l(v_s)v_k + l(v_k)v_s\};$ 
                end if;
            end do;
        end do;
    end if;
end do;
end if;
8.  $V_{current} := V_{current}^1 \cup V_{current}^2;$ 
9.  $S_{current} := S_{current} \cup \{l_i(x)\};$ 
10.  $S := S \setminus \{l_i(x)\};$ 
11.  $i := i + 1;$ 
12. if  $S = \emptyset$  then
    goto 14;
end if;
13. goto 5;
14. return  $U_{current}, V_{current}$ .

```

2.2 Some improvements

There are some tricks concerning the preparation of the system in order to lower the number of inequalities and/or variables.

Firstly, the system may have no occurrences of some of x_k , $k = 1, \dots, n$. In this case we can “clean up” the system and thus reduce the number of variables.

Secondly, we can avoid the linear subspace L of cone of solutions by performing the change of variables. This trick also enables one to simplify the original system of inequalities.

The dimension of L is $n - r$, where r is the rank of matrix of (1), as was mentioned above. Let us define new r variables $y_1, \dots, y_r$ to equal any r linear independent left-hand sides of (1) (for example, first r ones):

$$l_j(x) = -y_j \leq 0, \quad j = 1, \dots, r, \quad (8)$$

$$l_j(x) \leq 0, \quad j = r + 1, \dots, m. \quad (9)$$

By solving the system $\{l_j(x) = -y_j, j = 1, \dots, r\}$ for $\{x_1, \dots, x_n\}$ we obtain the $(n - r)$ -dimensional space of solutions

$$\begin{aligned} x_{i_1} &= f_1(y_1, \dots, y_r, x_{i_{r+1}}, \dots, x_{i_n}), \\ &\dots \end{aligned} \tag{10}$$

$$\begin{aligned} x_{i_r} &= f_r(y_1, \dots, y_r, x_{i_{r+1}}, \dots, x_{i_n}), \\ x_{i_{r+1}} &= x_{i_{r+1}} \\ &\dots \\ x_{i_n} &= x_{i_n} \end{aligned} \tag{11}$$

where $(i_1, \dots, i_n)$ is the permutation of indices $1, \dots, n$ (we don't know *a priori* which variables x_i are most likely to be solved for).

Upon substitution (10) the system (1) does not depend on $x_{i_{r+1}}, \dots, x_{i_n}$ because $l_{r+1}(x), \dots, l_m(x)$ are the linear combinations of the first r ones. Therefore, substitution (10) reduces the system to that of m inequalities for r independent variables $y_1, \dots, y_r$. The r inequalities of reduced system are simplified to be just $-y_i \leq 0$. This inequality subsystem has the *a priori* known solution E_r — the r -dimensional linear space base. Hence we may efface these inequalities from the reduced system. More precisely, solving the system we iterate Motzkin-Burger algorithm starting from the system of inequalities $\{-y_i \leq 0, i = 1, \dots, r\}$ and $U = \emptyset$ and $V = E_r$. Thus the system is reduced to of $m - r$ inequalities for r independent variables. Because $U = \emptyset$ at the start of algorithm, there is no need in any parts of algorithm except for the most complicated part that is the conversion of V to V^* when there is no u^- exists.

The application of the Motzkin-Burger algorithm yields a number of solutions of the reduced system. By means of $n - r$ substitutions (10) and $(x_{i_{r+1}}, \dots, x_{i_n}) = E_{n-r}^k$, where E_{n-r}^k are the base vectors of $(n - r)$ -dimensional linear space, we then obtain the solution set of the original system.

The case of $r = n$ is also of interest for simplifying the system despite that there is no lowering the number of variables. The system is reduced to that of $m - n$ inequalities for n independent variables in this case. The calculation procedure is repeated in full except for that there is no need to consider the substitution the $(n - r)$ -dimensional linear space base vectors to the several components $(x_{i_{r+1}}, \dots, x_{i_n})$ of any solution.

Also of interest is the case of $r = m$ where m is the number of inequalities. Upon the abovementioned substitution, the system is reduced to the diagonal one. Therefore, the whole system have *a priori* known solution in terms of new variables.

We therefore come to the algorithm of solving the system (1) with special preparation prior to the application of the Motzkin-Burger algorithm:

Input: $S := \{l_1(x), \dots, l_m(x)\}$ — the left-hand sides of the inequalities of (1), n — the space dimension.

Output: $U = \{u_1, \dots, u_t\}$ — the base of the maximal linear subspace L of the solution cone of (1),

$V = \{v_1, \dots, v_s\}$ — the set of generators for the strongly convex cone P of the solutions of the system (1).

1. Find all indices $Bad \subset \{1, \dots, n\}$ such that S has no occurrences of x_j , $j \in Bad$;
2. Renumber the indices (not encountered in Bad) of variables so that S explicitly depend on $n - |Bad|$ variables only;
3. Choose $Base$ — the maximal linear independent subsystem of $\{l_j(x), j = 1, \dots, m\}$; $r := |Base|$;
4. Solve $\{Base_i = -y_i, i = 1, \dots, r\}$ for $\{x_1, \dots, x_n\}$ to obtain set of identities (10);
5. $I := \{i_{r+1}, \dots, i_n\}$;
6. $U^\bullet := \emptyset$;
7. $V^\bullet := \{\underbrace{(1, 0, \dots, 0)}_{r \text{ components}}, \dots, (0, \dots, 0, 1)\}$;
8. **if** $r < m$ **then**
 - (a) Substitute (10) to S in order to obtain $S^\bullet$;
 - (b) Reorder the inequalities S such that $-y_i \leq 0$ are the first r ones.
 - (c) Iterate the part of Motzkin-Burger algorithm mentioned above excluding the items 1, 2, 3, 4, 6, considering $U_{current} = U^\bullet$, $V_{current} = V^\bullet$, $S_{current} = S^\bullet$, $i = r + 1$ as the initial condition.
- end if**;
9. $E := \{\underbrace{(1, 0, \dots, 0)}_{n-r \text{ components}}, \dots, (0, \dots, 0, 1)\}$;
10. For each element $e \in E$ substitute $\{y_1 = \dots = y_r = 0\}$ and $(x_{I_1}, \dots, x_{I_{n-r}}) = e$ into (10) and form $u := (x_1, \dots, x_n) \in U$;
11. For each element $v \in V^\bullet$ substitute $\{(y_1, \dots, y_r) = v\}$ and $(x_{I_1} = \dots = x_{I_{n-r}}) = 0$ into (10) and form $v := (x_1, \dots, x_n) \in V$;
12. return U, V .

2.3 Algorithm complexity

Let us not distinguish arithmetic and comparison operations. Let n be the number of independent variables, p be the number of elements in V at the current step, l be the number of v^- , $v \in V$, k be the number of v^+ , $v \in V$, q be the number of inequalities already examined by the current step and m be the number of inequalities in total.

The calculation of the value of $l(x)$ has the complexity $2n - 1$. If there exists such $u \in U$ that $l(u) \neq 0$, than the conversion $U \rightarrow U^\star$ and $V \rightarrow V^\star$ requires the calculation of $n - 1$ differences of the kind of $l(u^-)u_j - l(u_j)u^-$ with the total complexity $2 \cdot 2n + 1 = 4n + 1$. Therefore, the overall complexity of converting both lists is $2(n - 1)(4n + 1) \sim 8n^2$.

The case when no such $u \in U$ exists is of baffling complexity. Let us estimate the complexity of one iteration of this case as a function $f(p, q, n)$. For efficiency

reasons we suppose that all the values of $l_j(x) \in S$ for all $v \in V$ are computed beforehand in order to exclude repeated calculations.

Selection of v^- takes l operations. Next step — to select the pairs v^-, v^+ — requires $2kl$ more operations. The number of pairs reaches the maximum if $k = l = \frac{p}{2}$ so let $kl = \frac{p^2}{4}$ below.

For every pair v^-, v^+ we need to choose those inequalities $l_j(x)$ for which $l_j(v^-) = l_j(v^+)$ is true. This requires $2q$ operations. Then we should examine every pair on whether $p - 2$ elements of V do not zero all the chosen inequalities. Let the number of the chosen inequalities be as large as possible *i.e.*, $\frac{q}{2}$. Therefore, checking all the pairs have the complexity $\frac{p^2}{4}(p - 2)\frac{q}{2} = \frac{p^3q}{8} - \frac{p^2q}{4}$.

Let all the pairs satisfy the conditions above, then the overall complexity for all new the elements v is $\frac{3p^2}{4}$.

In total, $f(p, q, n) = pq(2n - 1) + \frac{p}{2} + \frac{p^2}{2} + \frac{p^3q}{8} - \frac{p^2q}{4} + \frac{3p^2}{4} = \frac{1}{8}p(p^2q + 10p - 2pq + 16qn - 8q + 4) \sim \frac{1}{8}p^3q$.

These intensive calculations are possible since $p_0 = 3$ because up to $p \leq 2$ there is only one (or no one) pair of generators for V . Therefore, up to one new generator is produced by algorithm for it to replace another.

As was mentioned, number p_k of elements $v \in V$ grows as $\frac{p_{k-1}}{2} + \frac{p_{k-1}^2}{4}$ on every k -th step. Iterating this function one can see that $p_k = p_k(p_{k-1}) = O(p_0^{2^{k-1}})$, so the worst-case complexity of pure iteration of the most complicated part of algorithm is $f(p_0, m, n) = O(mp_0^{(2^{m-4})^3}/8) = O(mp_0^{2^{3(m-4)}}) = O(mp_0^{2^{3m}}) = O(m3^{2^{3m}})$.

Practice shows that, in fact, such a terrible complexity is almost impossible to happen. There are many pairs rejected on every step. The number of pairs generally is not too large. Number of probe inequalities for every pair usually lower than $\frac{q}{2}$. Usually systems of full rank are incompatible for sufficiently large number of inequalities. Overall computation time nevertheless depends on n for the moderate systems. Despite of it, the data grows exponentially.

2.4 Practical experience

We implemented abovementioned algorithms in Maple as one package `motzkin_burger` consists of three user procedures: `Conehull`, `MB` and `CheckSolutions`. The first of these solves the problem to compute a set of generators for solution cone of system of inequalities. The second is the single Motzkin-Burger iteration. Last of these is the tool that allow user to check up the set of solutions on a correctness. Prototypes of these are

```
Conehull(L,x,n,options)
```

```
MB(L,U,V,x,n)
```

```
CheckSolutions(L,S,x,n)
```

Here L is a list of homogeneous polynomials of degree 1 in terms of variables x_i , n is dimension of space of solutions; U is the base of linear space of cone of solutions, V is the set of generators of strongly convex cone in latter cone; S is any solution set. Parameter **options**, at this moment, may accept only one value, “**as is**”, what gives an instruction do not perform change of variables.

Both **Conehull** and **MB** return an **exprseq** that consists of two 2-dimensional lists which are abovementioned lists U and V . **CheckSolutions** returns an **exprseq** too, but it might be interpreted in another way: first is the list of vectors that are true solutions whereas the second is the list of uncorrect solutions.

The timings presented in the table below are obtained in Maple 7 on computer based on Duron 700Mhz, 256 RAM. For every combination of (n, m, r) there was computed random system having these parameters, with sufficiently small integer coefficients. Here n is space dimension, m is the number of inequalities in the system and r is the rank of the system. Values t_1 and t_2 are times in seconds for solving the latter systems using or not optional parameter of **Conehull** procedure. All these systems are saved in attached to paper package codes text files.

space dimension, n	number of inequalities, m	rank, r	Conehull , option “ as is ”, t_1 , sec	Conehull , t_2 , sec
5	5	5	0.010	0.120
5	7	3	0.090	0.050
10	10	10	0.130	0.261
10	15	5	0.150	0.180
20	20	20	1.783	2.103
20	30	10	1.512	1.021
30	30	15	2.864	2.003
40	40	20	8.663	4.316
40	40	30	45.326	17.775
50	50	40	89.118	1816.392
50	50	45	73.766	1549.628

One can see that **Conehull** with option “**as is**” computes this examples with always increasing time (with rare exceptions). Without the option it behave more complicated: for every fixed n and m the case of the systems of full rank or “almost” full rank may be computed more faster than in the case of small rank. Of course, the option slows down the performance (this is the consequence of inefficient Maple **subs** implementation we are using) starting from some dimension, but we hope that the systems of larger dimension will be computed more faster with this option. Nevertheless, to improve this performance bottleneck is the main aim of further work.
